## Abstract

This note demonstrates that, for all compact convex sets, high-precision linear minimization can be performed via a single evaluation of the projection and a scalar-vector multiplication. In consequence, if  $\varepsilon$ -approximate linear minimization takes at least  $L(\varepsilon)$  real vector-arithmetic operations and projection requires  $P$  operations, then  $O(P) \geq O(L(\varepsilon))$  is guaranteed. This concept is expounded with examples, an explicit error bound, and an exact linear minimization result for polyhedral sets.

## 1 Introduction

**Notation 1.**  $\mathcal{H}$  is a real Hilbert space with inner product  $\langle \cdot | \cdot \rangle$  and induced norm  $\|\cdot\|$ . The set  $C \subset \mathcal{H}$  is nonempty, convex, and compact. The normal cone and indicator function of  $C$  are denoted  $N_C$  and  $\iota_C$  respectively (see, e.g., [2]). The projection operator onto  $C$  is denoted  $\text{Proj}_C: \mathcal{H} \rightarrow \mathcal{H}: x \mapsto \text{Argmin}_{c \in C} \|c - x\|$ . The set of linear minimization oracle points is  $\text{LMO}_C: \mathcal{H} \rightarrow 2^{\mathcal{H}}: x \mapsto \text{Argmin}_{c \in C} \langle c | x \rangle$ . For  $\varepsilon \geq 0$ , an  $\varepsilon$ -approximate LMO of  $x$  is a point  $v \in C$  such that  $0 \leq \langle v | x \rangle - \min_{c \in C} \langle c | x \rangle \leq \varepsilon$ .

**Assumption 1.** In-line with [13], this work assumes the ability to perform real number arithmetic operations. Suppose that, for all  $x \in \mathcal{H}$ , projection and  $\varepsilon$ -approximate linear

---

minimization can be performed over  $C$  using finitely many real vector-arithmetic operations. Let  $P$  and  $L(\varepsilon)$  respectively denote the smallest amount of operations required, i.e., the worst-case complexity for an “optimal” projection or LMO algorithm.<sup>1</sup>

In constrained first-order optimization, a guiding motivator for the development of Frank-Wolfe algorithms is the fact that their hallmark subroutine, the *linear minimization oracle* (i.e., a selection of the operator  $\text{LMO}_C$ ), is currently faster than projection oracles on some sets arising in applications, particularly in high-dimensional settings [3, 5, 7] (also, if projection is intractable, LMO is used to approximate it [9]). While several works suggest that for specific sets,  $P > L(0)$ , this principle does not appear to have been definitively established for all compact convex sets. In fact, regardless of approximativeness ( $\varepsilon > 0$ ) or exactness ( $\varepsilon = 0$ ), it appears there are no results pertaining to all compact convex sets that allow one to compare the computational complexity of linear minimization to that of projection.

The main contribution of this article is showing that, for any  $\varepsilon > 0$ , a high-precision  $\varepsilon$ -approximate LMO can be obtained via the use of one projection and a (real) scalar-vector multiplication, yielding the complexity bound  $P + 1 \geq L$  (hence, in finite-dimensional settings,  $\mathcal{O}(P) \geq \mathcal{O}(L(\varepsilon))$ <sup>2</sup>). The error bound in Theorem 2 explicitly depends on the radius and boundedness of  $C$ . It is further demonstrated in finite-dimensional settings that, when  $C$  is also polyhedral, projection is no faster than exact linear minimization, i.e., the stronger inequality  $\mathcal{O}(P) \geq \mathcal{O}(L(0))$  holds. The central approximation considered in this article comes from a geometric concept (see Figure 1) that is known (e.g., see [12]). Nonetheless, as far as the author is aware, the present error bound and complexity results appear to be new.

## 2 Relating linear minimization and projection

We begin with some basic facts; see, e.g., [2] for further background. Let  $x$  and  $z$  be points in a real Hilbert space  $\mathcal{H}$ . Then,

$$\begin{aligned} v \in \text{LMO}_C(z) = \operatorname{Argmin}_{c \in C} \langle c \mid z \rangle &\Leftrightarrow 0 \in \partial(\langle \cdot \mid z \rangle + \iota_C)(v) = z + N_C(v) \Leftrightarrow -z \in N_C(v) \\ &\Leftrightarrow \begin{cases} v \in C \\ \sup_{c \in C} \langle -z \mid c - v \rangle \leq 0. \end{cases} \end{aligned} \tag{1}$$

Similarly, we have the following familiar identity

$$p = \text{Proj}_C(x) \Leftrightarrow x - p \in N_C(p) \Leftrightarrow \begin{cases} p \in C \\ \sup_{c \in C} \langle x - p \mid c - p \rangle \leq 0. \end{cases} \tag{2}$$

---

<sup>1</sup> $P$  and  $L(\varepsilon)$  exist as limit points of monotonic sequences in  $\mathbb{N}$  bounded below.

<sup>2</sup>For the sake of presentation, (A) we suppress the dependence of  $P$  and  $L$  on  $C$  and the dimension of  $\mathcal{H}$  and (B) we also only use big- $\mathcal{O}$  notation in finite-dimensional settings; see [4].

**Proposition 1.** Let  $C \subset \mathcal{H}$  be a nonempty compact convex set. Then, for every  $x \in \mathcal{H}$ ,

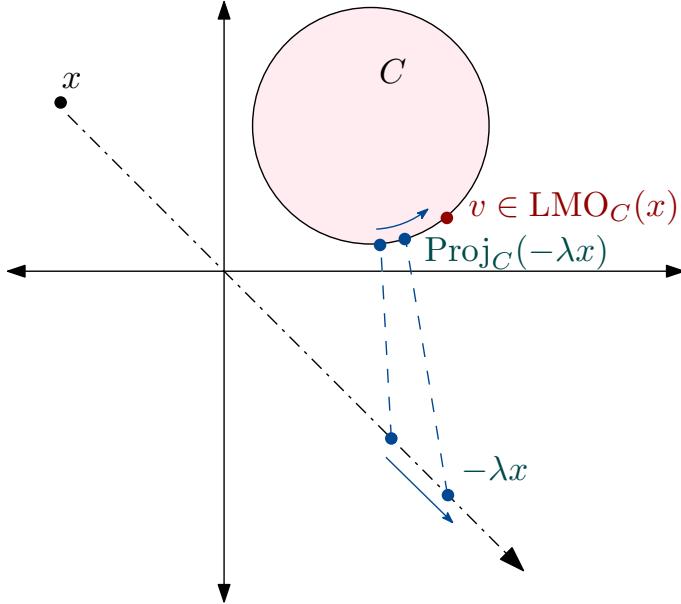

$$\text{Proj}_C(x) \in \text{LMO}_C(\text{Proj}_C(x) - x). \quad (3)$$

*Proof.* By setting  $z = \text{Proj}_C(x) - x$  in (1), we see from (2) that  $\text{Proj}_C(x)$  is a solution of the characterization in (1).  $\square$

**Remark 1.** Since linear minimization is not unique in general, evaluating  $\text{LMO}_C(\text{Proj}_C(x) - x)$  may not yield  $\text{Proj}_C(x)$  for every numerical implementation of  $\text{LMO}_C$  [1]. However, for a particular selection (in the sense of [2]) of the operator  $\text{LMO}_C$ , (3) is guaranteed to hold with equality instead of inclusion.

For  $\lambda > 0$  sufficiently large, one can approximate an element of  $\text{LMO}_C(x)$  with

$$\text{Proj}_C(-\lambda x). \quad (4)$$

**Fig. 1** As  $\lambda$  gets larger,  $\text{Proj}_C(-\lambda x)$  approaches  $\text{LMO}_C(x)$  for a shifted  $\ell_2$  ball.

Selecting the parameter  $\lambda$  can be guided as follows.

**Theorem 2.** Let  $x \in \mathcal{H}$  and let  $C$  be a nonempty, compact, and convex subset of  $\mathcal{H}$  with diameter  $\delta_C := \sup_{(c_1, c_2) \in C^2} \|c_1 - c_2\| \geq 0$  and bound  $\mu_C := \sup_{c \in C} \|c\| \geq 0$ . Then, for every  $\lambda > 0$  and every  $v \in \text{LMO}_C(x)$ ,

$$0 \leq \langle \text{Proj}_C(-\lambda x) | x \rangle - \min_{c \in C} \langle c | x \rangle \leq \frac{\|\text{Proj}_C(-\lambda x)\|}{\lambda} (\|v\| - \|\text{Proj}_C(-\lambda x)\|). \quad (5)$$

In consequence, we have  $\|\text{Proj}_C(-\lambda x)\| \leq \|v\|$  and for every  $\varepsilon > 0$ ,

$$\lambda \geq \frac{\min\{\delta_C \mu_C, \mu_C^2\}}{\varepsilon} \Rightarrow 0 \leq \langle \text{Proj}_C(-\lambda x) | x \rangle - \min_{c \in C} \langle c | x \rangle \leq \varepsilon. \quad (6)$$

*Proof.* Let  $v \in \text{LMO}_C(x)$ . By Proposition 1, and the definition of the LMO,

$$\text{Proj}_C(-\lambda x) \in \underset{c \in C}{\text{Argmin}} \langle c | \text{Proj}_C(-\lambda x) + \lambda x \rangle, \quad (7)$$

so, for all  $c \in C$ ,  $\langle \text{Proj}_C(-\lambda x) | \text{Proj}_C(-\lambda x) + \lambda x \rangle \leq \langle c | \text{Proj}_C(-\lambda x) + \lambda x \rangle$ . In particular,

$$\langle \text{Proj}_C(-\lambda x) | \text{Proj}_C(-\lambda x) + \lambda x \rangle \leq \langle v | \text{Proj}_C(-\lambda x) + \lambda x \rangle. \quad (8)$$

Dividing by  $\lambda$  and rearranging, then proceeding with standard norm inequalities yields

$$\langle \text{Proj}_C(-\lambda x) | x \rangle - \langle v | x \rangle \leq \lambda^{-1} (\langle v | \text{Proj}_C(-\lambda x) \rangle - \|\text{Proj}_C(-\lambda x)\|^2) \quad (9)$$

$$\leq \lambda^{-1} (\|v\| \|\text{Proj}_C(-\lambda x)\| - \|\text{Proj}_C(-\lambda x)\|^2) \quad (10)$$

$$= \lambda^{-1} \|\text{Proj}_C(-\lambda x)\| (\|v\| - \|\text{Proj}_C(-\lambda x)\|) \quad (11)$$

$$\leq \lambda^{-1} \|\text{Proj}_C(-\lambda x)\| \|v - \text{Proj}_C(-\lambda x)\|. \quad (12)$$

Since  $v$  is optimal, we can also lower bound (9) by 0; hence (5) follows from (11). An immediate consequence of (5) is that  $\|\text{Proj}_C(-\lambda x)\| \leq \|v\|$ . Proceeding with the bounds in (12), we have

$$0 \leq \langle \text{Proj}_C(-\lambda x) | x \rangle - \langle v | x \rangle \leq \lambda^{-1} \delta_C \mu_C. \quad (13)$$

On the other hand, dropping the negative term in (11) implies  $0 \leq \langle \text{Proj}_C(-\lambda x) | x \rangle - \langle v | x \rangle \leq \lambda^{-1} \mu_C^2$ . Hence, in either case of  $\lambda \geq \varepsilon^{-1} \min\{\delta_C \mu_C, \mu_C^2\}$ , (6) holds. In particular,  $\text{Proj}_C(-\lambda x)$  is an  $\varepsilon$ -approximate LMO.  $\square$

**Corollary 1** (Projection is no faster than approximate LMO). *Let  $\varepsilon > 0$  and suppose that Assumption 1 holds. Then  $P + 1 \geq L(\varepsilon)$ . In consequence, if  $P \geq 1$  and  $\mathcal{H}$  is finite-dimensional, then  $\mathcal{O}(P) \geq \mathcal{O}(L(\varepsilon))$ .*

*Proof.* From Theorem 2,  $L(\varepsilon)$  is bounded above by the cost of evaluating  $\text{Proj}_C(-\lambda x)$ , which is  $P + 1$ .  $\square$

**Remark 2.** *The type of bound provided by Theorem 2 is consistent with many algorithms that allow for inexact linear minimization, e.g., [5, 6, 11, 14].*

In general, Theorem 2 requires  $\lambda \rightarrow \infty$  to drive the error bound to zero (as demonstrated, e.g., for a shifted  $\ell_2$  ball). However, for some sets (e.g., the  $\ell_\infty$  ball), exact minimization is achieved for finite  $\lambda$ , i.e.,  $\text{Proj}_C(-\lambda x) \in \text{LMO}_C(x)$ .<sup>3</sup> As will be seen in Proposition 3, exact linear minimization for finite  $\lambda$  can be achieved more generally.

**Proposition 3** (Projection is no faster than exact LMO on polyhedral sets). *Let  $x \in \mathbb{R}^n =: \mathcal{H}$  and suppose that  $C \subset \mathcal{H}$  is compact, convex, and polyhedral. Then there exists a finite value  $\lambda^* \geq 0$  such that  $\text{Proj}_C(-\lambda^*x) \in \text{LMO}_C(x)$ . Further, if Assumption 1 holds, then  $P + 1 \geq L(0)$ ; if  $P \geq 1$ , then  $\mathcal{O}(P) \geq \mathcal{O}(L(0))$ .*

*Proof.* Without loss of generality  $C = \{x \in \mathcal{H} \mid Ax \leq b\}$  where  $A \in \mathbb{R}^{m \times n}$  and  $b \in \mathbb{R}^m$ . Let  $\nu = \min_{c \in C} \langle c \mid x \rangle$  and consider the problem of computing  $\text{Proj}_{\text{LMO}_C(x)}(\mathbf{0})$ , i.e., the minimal-norm element of  $\text{LMO}_C(x)$ :

$$\underset{\substack{z \in \mathcal{H} \\ Az \leq b \\ \langle z \mid x \rangle \leq \nu}}{\text{minimize}} \quad \frac{1}{2} \|z\|^2. \quad (14)$$

By [10, Theorem 11.15], strong duality holds and hence the perturbation function  $\mathbf{p}: \mathbb{R}^{m+1} \rightarrow [-\infty, +\infty]: y \mapsto \inf_{z \in \mathcal{H}} \{f(x) \mid Az - b \leq (y_i)_{i=1}^m; \langle z \mid x \rangle - \nu \leq y_{m+1}\}$  is stable in the sense of [8], i.e.,  $\mathbf{p}(\mathbf{0})$  is finite and there exists  $M > 0$  such that [8, pp. 8]

$$(\forall \xi > 0) \quad \frac{\mathbf{p}(\mathbf{0}) - \mathbf{p}(\xi, \dots, \xi)}{\xi} \leq M. \quad (15)$$

With an eye towards using [8, Theorem 3], we will use (15) to show that the partially-dualized perturbation function  $p: \mathbb{R} \rightarrow [-\infty, +\infty]: \xi \mapsto \inf_{z \in \mathcal{H}; Az - b \leq 0} \{f(x) \mid \langle x \mid z \rangle - \nu \leq \xi\}$  is also stable: this follows from the fact that  $p(0) = \mathbf{p}(\mathbf{0})$  and, for all  $\xi > 0$ ,  $p(\xi) \geq \mathbf{p}(\xi, \dots, \xi)$ , so

$$\frac{p(0) - p(\xi)}{\xi} = \frac{\mathbf{p}(\mathbf{0}) - \mathbf{p}(\xi)}{\xi} \leq \frac{\mathbf{p}(\mathbf{0}) - \mathbf{p}(\xi, \dots, \xi)}{\xi} \leq M, \quad (16)$$

as claimed. By [8, Theorem 3], there exists  $\lambda^* \geq 0$  such that

$$\text{Proj}_{\text{LMO}_C(x)}(\mathbf{0}) = \underset{\substack{z \in \mathcal{H} \\ Az \leq b}}{\text{Argmin}} \frac{1}{2} \|z\|^2 + \lambda^*(\langle x \mid z \rangle - \nu) \quad (17)$$

$$= \underset{\substack{z \in \mathcal{H} \\ Az \leq b}}{\text{Argmin}} \frac{1}{2} \|-\lambda^*x - z\|^2 = \text{Proj}_C(-\lambda^*x), \quad (18)$$

where (18) makes use of the fact that the minimization is not changed by addition of the constant  $\lambda^*\nu + \|\lambda^*x\|^2/2$ . This establishes that, for finite  $\lambda^* \geq 0$ ,  $\text{Proj}_C(-\lambda^*x) \in \text{LMO}_C(x)$ . In consequence, under Assumption 1, the computation required to perform  $\text{Proj}_C(-\lambda^*x)$  (namely  $P + 1$ ) is an upper bound on  $L(0)$ , which completes the proof.  $\square$

### 3 Conclusion

**Remark 3.** *In practice, using  $\text{Proj}_C(-\lambda x)$  to approximate an LMO point is not advisable since certain constants ( $\delta_C$  and  $\mu_C$  for Theorem 2;  $\lambda^*$  for Proposition 3) may*

be unknown, and faster methods may be available [3, 5, 7]. The main utility of these results are to establish a relationship between the optimal complexities  $P$  and  $L(\varepsilon)$  – not to provide an efficient algorithm for linear minimization.

While this note demonstrates two connections between the complexities of projection and linear minimization, the general relationship between  $P$  and  $L(0)$  warrants further investigation.

For some sets (e.g., singletons),  $P = L(0)$ . Hence, even though current evidence suggests that  $P > L(0)$  on a myriad of important sets [3], strict inequality cannot hold in general. Nonetheless, it remains an open question as to whether or not there exists *any* compact convex set such that its projection operator has a faster optimal runtime complexity than exact linear minimization.

**Question.** Does there exist a nonempty compact convex set such that  $P < L(0)$ ?

**Conjecture.** If the dimension of  $\mathcal{H}$  is finite, then  $L(0)$  is  $\mathcal{O}(P)$ .
